Background

Acute pain and agitation are common presentations that must be addressed in the prehospital setting by paramedics. Opioids are most frequently used to control acute pain but are highly addictive and patients can develop dependence even from short term use. For sedation, many different medications such as benzodiazepines and haloperidol are used, but their delayed onset of action is not desirable and side effects at effective doses (e.g. CNS depression) can be potentially harmful to the patients. In recent years, ketamine has been used as a safer alternative for prehospital analgesia and sedation in the military setting, but has not been studied sufficiently in the civilian setting to be a part of standard protocol nationwide [1]. Ketamine's primary action is to block glutamate from acting on the N-Methyl-D-Aspartate (NMDA) receptor resulting in a "dissociative anesthesia" state. It also works on other cellular processes such as hyperpolarization-activated cyclic nucleotide channels (HCN1), cholinergic, aminergic, and opioid systems making it useful for both analgesia and sedation [2].

Method

A review of recent literature from multiple electronic databases with the keywords "prehospital ketamine use" was conducted. The oldest article dates back to May 2013 while the most recent article was published March 2019.

Results

The articles reviewed either focused on the prehospital effectiveness of ketamine or compared ketamine to other widely used drugs. Ketamine has been shown to be effective when used alone or in conjunction with other drugs for a variety of injuries and comorbid conditions [1]. It can be used without intravenous access for rapid and safe sedation of violent and agitated patients with low respiratory or hemodynamic side effects [1,3,4]. Ketamine can be administered intramuscularly and works within three to four minute [4]. In a study done in 2018 comparing IV prehospital analgesics it was observed that ketamine provided a significant reduction in pain by 50% with a lack of adverse effects in comparison to fentanyl [5].

Another study done in 2016 measured that the median time to adequate sedation was 12 minutes faster with IM ketamine as compared to IM haloperidol for severe prehospital acute agitation. It was also noted that the only disadvantage of ketamine was higher intubation rates in comparison to haloperidol [6]. A third study in 2015 done in Iraq looked at the use of prehospital analgesia in rural trauma systems for serious injury patients. It was observed that ketamine had a significant better effect on improving systolic blood pressure as compared to pentazocine [7]. A study in 2018 looked at pain reduction using nitrous oxide with added intranasal ketamine versus intranasal steroids for hospital patients. It was reported the verbal numeric rating scale (VNRS) was significantly reduced after 30 minutes for the patients administered intranasal ketamine [8].

Despite its apparent effectiveness and safety, a large national survey of paramedics in the United States was conducted in 2018 that showed training related to use of ketamine was common, but few were authorized to use it by their agency’s protocol and even fewer had experience administering it [9]. Australia and New Zealand have been studying and using ketamine on the field by paramedics for several years. They have found decreased rates in intubation and pain scores after ketamine was introduced into their protocol [10- 12].

Conclusion

Ketamine administration is a more rapid and effective alternative to achieve analgesia and sedation in the prehospital setting with few clinical side effects. In comparison to other prehospital analgesia opioid like fentanyl and haloperidol it showed increased efficacy in reducing pain and improving blood pressure. It has yet to be introduced into prehospital protocol nationwide in the United States but has been part of protocol for years in Australia and New Zealand with overall improved outcomes in pain and intubation rates.
